To the Editor:

Microbiological methods such as Gram staining and culture of low respiratory tract secretions are necessary to detect the real bacterial pathogens that cause lower respiratory tract infections (LRTI). In many cases, Gram stain analysis may be unreliable to determine the cause of LRTI, and bacterial cultures provide adequate information. However, we herein report two cases of lower respiratory tract infections, diagnosed with the aid of microscopic examination of Gram staining, while routine cultures were negative in 48 h.

**Case 1.** A 74-year-old woman was referred to the hospital with the chief complaints of cough, fever, expectoration and episodes of hemoptysis lasting one month. A protected specimen brush (PSB) and a brochoalveolar lavage (BAL) were successively obtained. The samples were processed with Gram staining and routine cultures, done within 0.5 h of obtainment. On Gram staining, the organisms appeared as Gram-positive thin branching, beaded, coccoid filaments. Modified Ziehl-Nielsen staining (with 1% sulphuric acid) showed many acid-fast thin branching beaded filamentous structures, consistent with the morphology of *Nocardia* species. Meanwhile, the results of culture on blood agar and chocolate agar were negative at 37°C after 48 h. Small, dry, wrinkled, irregular, yellowish white colonies appeared on blood agar and chocolate agar after 72 h of incubation, which was also identified as *Nocardia asteroides* by standard bacteriological methods.

**Case 2.** A 42-year-old woman was diagnosed with systemic lupus erythematosus (SLE) in 2001 at the age of 32 years. In 2011, she was admitted to hospital with a two-week history of productive cough, wheezing, and fever. Culture and Gram staining of PSB and BLA were performed. Gram staining of all samples revealed a septate, hyphal organism, with dichotomous branching at an acute angle. Routine cultures at 48 h did not reveal any significant pathogens in the samples. At 72 hours of incubation, mycelial fronts of colonies grew on blood agar and chocolate agar. The characteristics of the isolate were identified as *Aspergillus fumigatus* by macroscopic aspects of texture, color and microscopic aspects, such as mycelium and conidium types, relationship between hyphae and fructification organs by lactophenol cotton bluemount. Some authorities (e.g. Infectious Diseases Society of America [IDSA]) recommend sputum Gram staining and cultures for pathogen identification. In many clinical microbiology laboratories, the culture of respiratory tract secretions is incubated routinely for 48 h. However, some pathogenic organisms of LRTI such as *Nocardia* species and fungi, need incubation for a longer period. Nocardia and fungal infections are important causes of LRTI in the immunocompromised hosts. People on chronic steroid therapy, those with cancer, organ or bone marrow transplants, or infected with human immunodeficiency virus (HIV) are at risk. The diagnosis of those infections is often based on the results of microbial pathogens analysis. As Nocardia and fungal cultures require considerable longer incubation periods, the routine respiratory secretion culture of *Nocardia* species and fungi is generally negative. In the two cases presented, the cultures were prolonged to 72 h, because Gram staining of samples demonstrated that there were pathogens present. We propose that Gram staining paired to routine culture is valuable and should be encouraged in clinical practice for the management of lower respiratory tract infections. In specific cases, especially among immunocompromised hosts, the search for atypical microbial etiologies using Gram staining, can become extraordinarily valuable.
